

How climate change is affecting sea levels

Climate Science Communications Group Committee

Briefing paper: Issue 10

Acknowledgements

The Royal Meteorological Society would like to thank Matt Palmer, Jonathan Gregory and Tamsin Edwards for reviewing the paper.

Also, thank you to members of the Climate Science Communications Group including Erik Mackie, Emily Shuckburgh, Dan Jones and David Vaughan for all their efforts and hard work in bringing this paper together.

How climate change is affecting sea levels

Why is sea level rise important?

Sea level rise increases the frequency and severity of storm surges and coastal flooding, causing serious damage to critical infrastructure and leading to the displacement of coastal communities around the world. Globally, more than 600 million people live in low-lying coastal areas at less than 10 metres elevation, and the population of these regions is expected to exceed 1 billion by 2050. In the UK, current annual damages from coastal flooding are estimated at over £500 million per year, and costs of damage are likely to increase under projections of future sea level rise.

How much and how fast is sea level rising?

Since 1900, global mean sea level (GMSL) has risen by approximately 20 cm. The rate of sea level rise has increased throughout the 20th and early 21st centuries, and it is currently rising at about 3.6 cm per decade. Sea level rise varies locally from the global average, however, as a result of multiple factors including changes in ocean temperature and circulation, gravitational effects, and vertical land movement. Once vertical land movement is taken into account, mean sea level regionally around the UK has risen by approximately 1.4 cm per decade since 1900.

What causes sea level to rise?

Increasing global surface temperatures, resulting from human emissions of greenhouse gases (GHGs), cause the sea level to rise through two main processes. Firstly, the ocean warms up along with the surface temperature, causing the ocean to expand as it warms and therefore increasing sea level. Secondly, water that is currently stored on land in the form of ice is added to the oceans as glaciers and ice sheets melt, further increasing sea level.

How much will sea level rise in future?

The Intergovernmental Panel on Climate Change (IPCC) projected in its recent Special Report on the Ocean and Cryosphere in a Changing Climate that GMSL rise by 2100 will likely lie within the ranges of 29-59 cm or 61-110 cm (relative to 1986-2005) for a low or high emissions scenario respectively. In addition, the IPCC Special Report on Global Warming of 1.5°C stated that GMSL rise by 2100 will likely be around 10 cm less in a 1.5°C warmer world when compared with a 2°C warmer world. The latest regional projections for the UK were published in the UKCP18 report, with 2100 ranges of 8-49 cm (low emissions scenario) or 30-90 cm (high emissions scenario) for Edinburgh, and 29-70 cm (low) or 53-115 cm (high) for London. The largest source of uncertainty in all these projections is currently associated with quantifying the additional sea level rise contribution due to instabilities of the West Antarctic Ice Sheet, which remains the subject of ongoing research.

Beyond 2100, sea level will continue to rise for many centuries, even if GHG emissions are reduced to net-zero in line with the 2015 Paris Agreement targets to limit global warming to 1.5°C or 2°C. However, the magnitude and the rate of this committed long-term sea level rise depend strongly on near-term emissions reductions in coming decades. The sooner net-zero or net-negative GHG emissions are achieved, the more the amount of long-term sea level rise can be limited. If GHG emissions are left unchecked, the rate of sea level rise will further accelerate.
